Abstract

In recent years tomatoes have been peeled using steam and lye. Both are costlier, less environmentally friendly and highly polluting techniques. Thus, more sustainable alternatives should be sought after. Among these alternatives is radiative heating. To appropriately design the system for dry peeling, several typical operational characteristics of the process in issue must be estimated. The analytical model presented allows estimates to be made through closed-form relationships between the parameters involved. The analysis is based on the use of an appropriate theoretical model, which facilitates the solution to the proposed problems. Through the approximate solution of the analytical problem, we will analyse: the angular speed $\Omega$, the temperature fluctuations $\Delta T_{\Omega}$, the process time $t_{\pi}$. These estimates are then used to derive a specific model for a control of process. The temperature profile (through an approximate solution) associated with the process that provides the optimum peel quality was utilized as a guide for the regulation system. A control system used the code to extract a specific temperature, and based on surface tomato temperature readings, controlled a brushless motor using a logic strategy. The regulating system can adjust the rotation speed, and hence the heating intensity, even under less than perfect operating conditions in order to obtain the appropriate profile temperature. The controlled temperature profile yielded an average temperature of 66.3°C, while the reference case yielded a temperature of 67°C. Additionally, it was found that the temperature inaccuracy decreased with each rotation, ranging from 2.5 °C at 2$\pi$ to 0.3 °C at 16$\pi$. As a result, the peeling procedure is standardized in time, temperature, and quality.

Keywords: Dry peeling system; integral method; process control, approximate solution

1. Introduction

Major issues that plague the sustainability of the tomato processing industry include energy consumption, wastewater management, and pollution [1–3]. With the development of advanced infrared dry peeling technology, the traditional hot lye method for peeling tomatoes can be replaced. This process relies on infrared heating panels to quickly heat up tomatoes, resulting in a thinner thickness of peeled-off skin and slightly firmer texture of peeled tomato. The IR dry-peeling method is rapidly adopted by food processors, due to its sustainable advantages like high efficiency and negligible water use [4, 5]. By irradiating the tomato surface with infrared radiation and selecting a suitable value of power density, temperature and time, it is possible to increase the Young’s modulus of the peels. As a result, the adhesiveness of the peel is reduced. These findings demonstrated the effectiveness of the novel IR dry-peeling process for tomatoes [6]. Producing high quality peeled tomatoes is a challenging task, especially with the variety of tomato types. However, some critical aspects of peeling tomatoes using infrared radiation heating were outlined by [7]. Wishing to perform successful infrared peeling requires to realize both rapid and uniform heating on the tomato surface. An infrared heating system was designed to be installed in a food processing facility. The purpose of this research is to improve the heating uniformity of tomatoes transported along the conveyor belt, in order to obtain an optimal design of infrared heating systems. For this purpose, the irregular shape of tomatoes and their different expositions to the heating source when transported along the conveyor belt are to be considered. In this context, a typical configuration for industrial peeling is realized by means of a plane matrix of infrared emitters [8, 9]; looking at tomatoes in relative motion, they have been found to rotate on the belt when processed. To retrieve tomato thermal response to infrared heating, a numerical approach is necessary due to the complexity of the geometry. Previously, the authors attempted to describe the process using an analytical model: an infinite body subjected to a suitable source of pulsating heat was considered because the proper time scale was small [10, 11]. For peeling purpose, it proved useful to assume that the heating process would end a specified temperature was reached [4, 8, 12]. Achieving the best heating uniformity also means considering rotation speed and relative position to the source. To ensure uniform heating, a system for a rotation speed regulating has been proposed. After dimensioned the system and got the values of the parameters which enable to achieve the optimal temperature profile, which thus assures the proper heating uniformity and excellent quality of the product, the control logic has been established which allows us to obtain a peeling process with very comparable temperature profiles to the reference one. De facto, the
emissivity value and therefore the amount of heat transferred are influenced by factors like the size of the tomatoes, the existence of processing residues on the lamp’s surface, and others [13, 14]. In order to regulate the intensity of the heat transferred, the rotation speed was adjusted.

To achieve this, the surface temperature, the logic control, and the temperature value pertaining to the reference profile must be delivered to the regulating system. A pyrometer, a mathematical model, and an approximation solution are used to supply the first, second, and third parameters, respectively. The analytic solution appears rather involved [10, 11], which affects the calculation times, thus a further approximate approach to the same problem is attempted in order to obtain an easy-to-handle solution, and therefore less run time. Since the peeling process typically takes place at a number of revolutions of n ≃ 10 rpm [4, 8, 12], the regulation system will have to act approximately every 6 s. The relatively long calculation times, about 2 s, moreover and the solution’s complex structure make the analytical solution unusable for the proposed regulation system. While the approximate solution is obtained almost instantly. It is therefore very simple and rapid to provide the code with the function that represents the approximate solution of the problem. In this way, it is feasible to overcome the limitations noted in the literature, in which, after the ideal peeling parameters have been determined, the process always occurs under the same conditions, without taking into account the variation of thermal power transferred as the emissivity varies (different diameters, process residues on the lamp surface, etc.). As a result, the method is highly dependent on the emissivity value and fails to produce a quality-standardized output. Instead, by using the dry peeling temperature control system, the peeling productivity can be significantly increased by making the process quality standardized.

2. Materials and Method

   The experimental setup of Figure 8, relating to the peeling of tomatoes with radiation, belongs at the first step of Pan’s activity, Li et al. [8, 12, 15, 19].

   ![Experimental Setup Diagram](image)

   Figure 1. The experimental setup.

   It consists of two main sections: IR heater, and rotating rollers. Curved ceramic emitters were adopted in the prototype equipment to enhance the IR heating intensity and the overall heating uniformity of tomatoes [8, 9, 18, 19]. Specifically created software (7.1 LabView®, National Instruments Corp., Austin, Texas) was employed for both data acquisition and reduction. The code collects the temperature data, detected by the pyrometers, for control purposes. In particular, the first pyrometer is used to obtain the temperature of the lamp, and therefore to be able to evaluate the power transferred by it. The second supplies the surface temperature of the tomato, required for regulation system. At this point, the code extracted a specific system, and based on such temperature reading, the computer program controlled the brushless motor, then the revolution number n, with a DAQ board (AT MIO 16XE50, National Instruments, Austin, Texas) by means of a specific logic strategy.

3. Mathematical Formulation

   The theoretical study of the thermal problem involving the radiative heating of the tomato began with analytical modeling [16]. The non-linear exchange between various radiative surfaces makes heat transfer modeling in tomato IR heating difficult [21]. Several assumptions were made in the development of the heat transfer model to simplify it and reduce computational times. Such assumptions have been frequently used by researchers to develop heat transfer modeling during IR heating of food [21-24].

   - Rapid processing determines only surface peripheral warming up.
   - Flesh and peel materials were homogeneous, isotropic, and had similar thermal properties. For lye peeling, the surface temperature of tomatoes was assumed to be equal to the temperature of peeling solution[12].
   - Constant thermal proprieties: It has been verified that the sensitivity of the temperature field to variations in properties has no effect on the thermal aspect of the problem under examination.
   - Generally, tomatoes used in this study were longer in longitudinal direction (stem-blossom end) than radial direction [22]. Since the tomatoes were lined up in the longitudinal direction, the long row of tomatoes were considered as an infinitely long cylinder (i.e., the variation in the diameter of tomatoes was neglected).
   - Tomato was opaque to thermal radiation (no transmission) and all incident energy was absorbed at the surface of tomato with a small reflection of incident energy (reflectivity of tomato is about 5%) [22].
   - All participating radiating surfaces were diffused-grays surfaces based on the enclosure theory, which meant that each participating object could emit to and absorb radiation from each other.
   - Hot air between emitter and tomato was transparent and did not interact with IR radiation passing through it. In other words, the proposed model involved heat transfer with surface to surface radiation among diffused surfaces through nonparticipating medium.
   - Heat transfer within the tomato occurred only by conduction.
   - Heat transfer at tomato surface occurred by radiation between emitter and tomato and convection between air and tomato. Air temperature (T∞ ) remained constant.
   - All radiation heat was incident on tomato surface only (i.e. zero penetration depth).
   - Heat of generation due to respiration was neglected because it is very small compared to the total thermal energy received by tomato during IR heating.
   - Mass transfer (moisture loss) was so small that the rate of heat loss due to evaporation could be neglected. Therefore, heat transfer due to evaporation (qevap) during IR heating of tomatoes was assumed to be zero (qevap = 0) [22, 26]. Thus the tomato under test is modeled as a purely conductive radiation semi-infinite body 1-D model.
The analytical approach has its purpose of estimating the process parameters and at the same time to understand the phenomenon in question. To thermally model the tomato it is necessary to carry out an evaluation of the thermophysical properties which should be close to those of water. The thermophysical properties are evaluated using the typical food constituents: water, proteins, fats, carbohydrates, fibers, and ashes. In 1986 Yonghee Choi and Martin Okos of the Purdue University in the USA, on the basis of experiments and theoretical-analytical checks [17], developed mathematical models in a range of validity between -40 and +150°C for the estimation of thermophysical properties of foods based on their composition. Table 1 shows the mathematical models for estimating the following properties as function of temperature:

- thermal conductivity (k)
- thermal diffusivity (α)
- density (ρ)
- specific heat at constant pressure (c_p)

</table>

The density of foods ρ can be calculated with the relationship:

\[ \rho = (1-\zeta) / \sum(x_i/p_i) \]  

(1)

where \( \zeta \) is the porosity, \( x_i \) and \( p_i \) are respectively the mass fraction and density of the different food constituents. The specific heat of the food above the freezing temperature can be obtained from the weighted average of the specific heats of the constituent components according to the Eq. (2):

\[ c_p = \sum c_i x_i \]  

(2)

where \( c_i \) and \( x_i \) are the specific and the mass fraction of the different food constituents.

Several models for the estimation of \( k \) have been developed to take due account of the fibrous structure of many foods. In particular Murakami and Okos, in analogy with parallel or series connections of the electrical resistances, have proposed models that consider the anisotropy of the materials. The parallel model (p.m) is the sum of the thermal conductivities of the constituents \( k_i \), multiplied by the respective fractions in volume according to the Eq. (3):

\[ k_{eq} = \sum x_i v_i k_i \]  

(3)

The volume fraction can be obtained from the following relationship:

\[ x_i v_i = (x_i/\rho_i) / \sum (x_i/\rho_i) \]  

(4)

The mass fractions of the individual tomato constituents reported in one of the works by Pan et al [8], were obtained from the “United States Department of Agriculture Food Composition Databases” (2010 USDA Nutrient Database) Table 2. Considering the temperature equal to 25°C and using the above equations, the thermophysical properties are calculated for each component and having determined the relative volume fractions, those of the tomato.

For tomato we obtain: \( \rho = 1014.8 \text{ kg/m}^3 \), \( k = 0.596 \text{ W/(mK)} \) and \( c_p = 4032 \text{ J/(kgK)} \). The results clearly show how strongly similar the characteristics of the tomato are to those of water.

In order to verify the validity of the parallel model, used following the assumptions made, the properties were verified to correspond to those derived from [21], obtained through the empirical formulas described by Singh and Heldman [27].

</table>

As shown in the Table 3, the error incurred while utilizing the parallel approach for thermal conductivity is no more than 4%. Therefore, the applied methodology can be regarded as accurate given that the results of the sensitivity analysis demonstrate that a 10% variation in the properties corresponds to a 3.1% variation in the size itself. Consequently, the error made taking into account the constant properties is also small.

Typically, a very short warm up period of no more than 60 seconds is required for successful peeling of surfaces at
temperatures as high as 100°C [4, 8, 12, 19]. For tomato, assuming the thermo-physical properties of water apply, it can be easily demonstrated that thermal penetration depth will be limited to a few millimeters under the tomato skin, thereby permitting the semi-infinite body model to be applied [10]. Convective heat transfer also occurs at the boundary due to cycling radiative heating extended to the first half period of the sinusoidal source. Our study is concerned with a semi-infinite medium with combined third and second kind boundary conditions, incorporating both convection and periodic heating, Figure 2.

One-dimensional heat conduction and constant thermal properties are considered. The medium is assumed initially in equilibrium with the ambient at temperature $T_0$. In order to describe the heating felt by the rotating tomatoes, the surface at $x = 0$ is assumed to be exposed to a periodic on/off heat flux with $\frac{1}{2}$ duty cycle; when the source is on, i.e. in the first half period, the heating intensity is assumed to vary sinusoidally with time, while it is zero in the second half, Figure 3.

Therefore, periodic nonhomogeneous boundary conditions are required, which highlight the semi-amplitudes and characteristic angular speeds $\Omega$ of tomato rotation. During the peeling process, the temperature penetration depth is easily checked to ensure that it is confined to the very first layers of the tomato skin, which justifies the semi-infinite slab model [10, 11]. When constant properties are considered and heat is transferred using internal conduction, dimensionless energy balance equations and associated boundary conditions have nonhomogeneous linear properties:

$$\frac{2}{\sqrt{\pi}} \int_0^\tau \hat{q}(\tau) \, d\tau = \hat{q}(\tau) - B_i \left( \theta - \theta_f \right)$$

(6)

$$\theta(\xi, \tau = 0) = 0$$

(7)

$$\theta(\xi \to \infty, \tau) = 0$$

(8)

where the following dimensionless parameters have been introduced: $\theta = (T - T_0)/DT$ is a dimensionless temperature, $T_0$ is the initial temperature; the group $DT = q_0x_0/k$ [K] is a reference temperature difference, $q_0$ is the heat flux, and $x_0 = \sqrt{2\alpha T}$ [m] a reference length; $k$ [W m$^{-2}$ k$^{-1}$] is thermal conductivity and $\alpha$ [m$^{-2}$ s$^{-1}$] is the thermal diffusivity of tomato; the reference time, $t_0 = \beta^{-1}$ was chosen such as the dimensionless time resulted $\tau = t0^{-1}$ [rad], being $\beta$ [rad s$^{-1}$] the angular velocity of the source; the dimensionless space variable was defined such as $\xi = x/x_0$ and, finally, $\hat{q}(\tau) = \sin(\tau)/[1+\sin(\sin(\tau))]$ is the normalized wall heat flux, and $B_i = h x_0/k$ is the Biot number.

The solution was be obtained as the sum of two partial solutions. The analytical solution of both is obtained by the application of the Laplace transform technique. The full solution (Eq. (9)), obtained and validated in the previous works [10, 11, 20] (Figure 4), turns out to be was:

$$\theta(\xi, \tau) = \theta_1(\xi, \tau) + (1 + (-1)^h) \theta_2(\xi, \tau) = -2 \sum_{i=0}^\infty (-1)^i \hat{\theta}_i(\xi, \tau)$$

(9)

with

$$\hat{\theta}_i(\xi, \tau) = \left[ \int \frac{e^{2(x-t)}}{\sqrt{4\pi(t-\tau)}} B_i e B_i \sqrt{2\xi} + B_i^2(\tau-t) \right] \times \text{erfc} \left( \frac{\xi}{\sqrt{2(\tau-t)}} \right) \sin(\tau) d\tau$$

(10)

The term

$$\theta_1(\xi, \tau) = \theta_0 \left( \frac{e^{-\frac{\xi^2}{2\tau^2}}}{\sqrt{2\pi}} - B_i^2 \frac{\xi}{\sqrt{2\tau^3}} + \text{erfc} \left( \frac{\xi}{\sqrt{2\tau^3}} \right) \right)$$

represents the thermal response due to the convective heat transfer driven by the initial temperature excess $\theta_0 = (T_0 - T_f)/DT$, relatively to ambient temperature $T_f$, $n$ is intervals of amplitude $\pi$ over which $\hat{q}(\tau)$ remains continuous and $\tau$ is the dummy variable of convolution.

The term $\theta_1$ is obtained from the particularization of Eq. (10) at process time. As expected, the solution depends not only on the values at time $\tau$, but it also depends on the heating previously experienced at each revolution ($\theta_{1\text{rev}}$), i.e. at each $\tau = \pi \tau$. The temperature field is unsteady due to the spatial and temporal

Figure 2. A schematic representation of the problem.

Figure 3. The dimensionless shapes for heat flux.
coordinates and the Biot number. The oscillating trend of the temperature profiles is represented in the Figure 3 in correspondence with the surface \((\xi=0)\) for different values of the Biot number. The Figure clearly shows that different entities of cooling have different thermal responses. The greater the Biot number, the more both temperature levels and the amplitude of the oscillations decrease \((\Delta \theta_{\text{Bi}=0} = 0.80, \Delta \theta_{\text{Bi}=0.5} = 0.53)\). Can be further observed that the phase shift with respect to the heat flux decreases with Bi number \((\phi_{\text{Bi}=0} = 0.72, \phi_{\text{Bi}=0.5} = 0.46)\) [11]. The analytical solution was used to validate the approximate solution.

By imposing that the approximate equation satisfies the integral and applying a boundary conditions, we obtain:

\[
0.1014 B_1 \cos \left(0.8358 - 1.024 B_1 \right)
-0.2078 \cos \left(0.8358 - 1.024 B_1 \right) \\
+ \left(6.601 \times 10^3 \right) B_1 = 0 \\
+ \left(1.5635 \times 10^3 \right) a''(\xi) + 0.5795 B_1^2 \\
+ 4.682 B_1 - 0.1014 B_1 \cos \left(1.024 B_1 + 124.828 \right) \\
+ 0.2078 \cos \left(1.024 B_1 + 124.828 \right) - 3.302
\]

\(b.c.1.\) \[\frac{\partial \theta}{\partial \xi}\bigg|_{0, \tau} = \hat{q}(\tau) - B_1 \left(\theta - \theta_j\right)\]

\[
\Rightarrow -a'(0)\text{erf}(\tau^{1.5}) = \frac{1}{2} \left(1 - \text{sign} (\sin (\tau))\right) \sin (\tau) \\
- B_1 \left(0.230 - 0.352 B_1\right) \sqrt{\tau} \\
- (1-1.167 B_1) (0.177 - 0.248 B_1) \text{erf (\tau)} \\
+ a(0)\text{erfi}(\tau) + \left(0.186 - 0.156 B_1\right) \sin (2.112 - \tau)^3
\]

\(b.c.2.\) \[\theta^*(\xi = 0, \tau) = 0\]

\[
\Rightarrow \left(1-1.167 B_1\right) \left(0.177 - 0.2483 B_1\right) \text{erf (\tau)} \\
+ \sqrt{\tau} \left(0.2307 - 0.352 B_1\right) \\
+ \left(0.1867 - 0.156 B_1\right) \sin (2.112 - \tau) \\
+ \left(0.235 - 0.157 B_1\right) \sin (\tau)^3 \\
+ \left(0.207 - 0.101 B_1\right) \sin (0.418 - \tau - 0.512 B_1)^2 \\
+ \left(0.1775 - 0.2483 B_1\right) \text{erf (-\tau)} \left(1-1.167 B_1\right)
\]

with \(a(\xi)\) unknown function which is obtained as follows. Eq. (5) has been integrated into the time coordinate and \(\tau\):

\[
\tau = 20 \pi \int_{\tau=0}^{\frac{\partial^2 \theta}{\partial \xi^2} - 2 \frac{\partial \theta}{\partial \tau}} d\tau = 0
\]

By solving the differential equation system (Eqs. (14)-(16)), the solution \(a(\xi)\) is obtained (Eq. (17)).
\[
a(\xi) = \frac{1}{\left(-3.32 \times 10^2 B_1 - 5.11 \times 10^2\right) \text{erf}(\xi^{1.5})} \times 0.29 e^{-153.9 e^{307.8 e^{307.8 \xi}}} \text{erf}(\xi^{1.5})

- 5.198 \times 10^{20} e^{307.8 \xi} \sin(2.11 - \tau)
\]

\[
+ 5.728 \times 10^{20} \sin(2.11 - \tau) \cdot \sin(2.11 - \tau) + 5.728 \times 10^{20} \sin(2.11 - \tau)
\]

\[
- \left(1.167 B_1 \right) \left(0.177 - 0.24 B_1 \right) \text{erf}(\xi^{1.5})
\]

\[
+ \sqrt{\tau} \left(0.230 - 0.352 B_1 \right) + 0.186 - 0.156 B_1 \left(0.512 B_1 \cdot \tau + 0.417\right)
\]

\[
+ 0.235 - 0.157 B_1 \sin(2.11 - \tau)
\]

\[
+ 0.207 - 0.1014 B_1 \sin(2.11 - \tau)
\]

\[
+ 0.443 - 0.255 B_1 \sin(2.11 - \tau)
\]

\[
- 0.158 - 0.180 B_1 \sin(2.11 - \tau)
\]

The complete solution is then derived using Eq. (12). It can be shown that the temperature profile resulting from the approximate solution (Eq. (12)) differs from that resulting from the corresponding analytical solution (Eq. (9)) by no more than 1.5% for Bi=0.5 and 1.2% for Bi=0 (Figure 5).

Temperature profiles as a function of revolution number were calculated using a dimensional formulation (Figure 6).

The dimensional temperature profile was evaluated assuming \(T_0 = 20 \, ^\circ\text{C}, \dot{q} = 40000 \, \text{W/m}^2\). The value of the heat flux was estimated by assimilating the emitter and the two-body tomato characterized by \(\varepsilon = 1\) and uniform temperatures equal to 650\(^\circ\text{C}\) and 60\(^\circ\text{C}\), respectively [13, 14, 18]. In the case of the tomato, it is considered an arbitrary thermal level corresponding to an intermediate value between the initial temperature and the final temperature assumed by it. The temperature level and, thus, the temperature fluctuation \(\Delta T\) are reduced as \(n\) grows, as predicted, with sensitivity decreasing as \(n\) increases (Figure 5). In fact, for the same change in the number of revolutions, in this example from \(n=3\) to \(n=5\) rpm and from \(n=11\) to \(n=13\) rpm, at the lowest number of revolutions, temperature fluctuations are greatest. The temperature fluctuation \(\Delta T\) for each lap was also evaluated for different rpm (Figure 7).

The exponential function is used to fit the data (Table 4):

\[
\Delta T_n(\tau) = a \cdot \tau^b + c \cdot \tau
\]

\[
\text{Figure 5. The dimensionless surface temperature at } \xi = 0 \text{ analytic vs approximate solution.}
\]

\[
\text{Figure 6. Surface temperature at } \xi = 0 \text{ at different rpm values, } 0 < \tau < 2\pi.
\]

\[
\text{Figure 7. The Temperature Fluctuation as Function of } \tau \text{ at Different Values of rpm.}
\]
For regulation purposes, so, it is useful to evaluate, for each revolution, the temperature fluctuation $\Delta T_{r}(n)$ as a function of $n$ (Figure 8, Table 5).

As a consequence, after figuring out the number of revolutions necessary to get the best peeling quality, the dimensional temperature profile, obtained from the approximate solution with $n = 10$ rpm and $Bi = 0$, was used as a reference for the regulation system. Indeed, in the case of natural convection the value of $Bi$ is very small, therefore for ease of calculation it was chosen equal to 0 [10, 11]. Particularizing the Eq. (12) in light of the considerations made, it is obtained:

$$ T_{\text{targ},r} = 6\left(0, \tau \right) - DT_{\text{ref},n=10} + T_{0} $$

(21)

with $DT_{\text{ref},n=10} = \dot{q}_{r} \cdot \tau_{\text{ref}} / k$. For regulation purposes, the error is evaluated at each revolution as follows:

$$ err_{r} = T_{\text{targ},r} - T_{\text{sensor},r} $$

(22)

where $T_{\text{sensor},r}$ is the surface temperature of the tomato detected by the sensor and $T_{\text{targ},r}$ is the temperature corresponding to the reference temperature profile at the $i$th period (Eq. (21)). Thus, the temperature target fluctuations value ($\Delta T_{\text{targ},r}$) necessary to reach the target temperature in the next period is obtained:

$$ \Delta T_{\text{targ},r+2\pi} = T_{\text{targ},r+2\pi} - T_{\text{sensor},r} $$

(23)

By particularizing Eq. (19) at time $i+2\pi$, the value of $n$ to be used for regulation is obtained as shown:

$$ \Delta T_{\text{targ},i+2\pi} + err_{r}/2 = A_{(i+2\pi)}n^{B(i+2\pi)} + C_{(i+2\pi)}n $$

(24)

The equation that governs the control logic is represented by Eq. (24).

A straightforward illustration may be used to evaluate the method’s efficacy. The value of emissivity is influenced by the geometric irregularity of the tomatoes and/or the presence of processing residues on the lamp's surface, which results in a reduction in the heat power transferred [10, 11, 19]. It is assumed that in the same working conditions ($n = 10$ rpm) the value of the radiative heat flux decreases to the value of $\dot{q} = 33000 \text{ W/m}^2$. The decrease in the heat flow leads to the decrease in a reference temperature difference ($DT_{\text{ref},n=10} = \dot{q} r \cdot \tau_{\text{ref}} / k$), consequently the relative temperature profile ($T(0, \tau) = T_{0} + \dot{q}(0, \tau) - DT_{\text{ref}}$) is lower than the reference one ($DT_{\text{ref},n=10} < DT_{\text{ref,n=10}}$): heat flux reduces and hence the rate of temperature rises decreases. As a result of not enabling the regulation, the temperature profile $T(0, \tau)$ seen in Figure 9 is achieved. The peeling process, as shown, occurring at lower level temperature respect to reference profile, with a consequent lengthening of the process time. Ad-hoc regulation is implemented to keep the temperature profile similar to the reference one even if work conditions change. The number of revolution decreases when the temperature falls below the reference temperature, and vice versa.

Therefore, at the end of the first revolution ($i = 2\pi$), the error is evaluated (Eq. (22)):

$$ err_{2\pi} = T_{\text{targ},2\pi} - T_{\text{sensor},2\pi} = 34.1 - 31.6 = 2.5 $$

(25)

In this way, an estimate of the temperature fluctuation $\Delta T_{r}(n)$ for each period as the number of revolutions varies is obtained.

4. Logic Control

To realize successful peeling, surface temperatures are to be raised to values as high as 100°C in a very short warming up period, typically no more than 60 s [4, 8, 12]. By setting the revolution number to 10 rpm and the thermal flow value to 40000 W/m², the peeling process is completed in 51 s.

$$ \tau_{\text{end}} = \tau_{\text{end,ref}} = 17\pi(3/\pi) = 51 \text{ s} $$

(20)
The thermal response ($T_{sensor,i}$) is the result of simulated (through approximate solution) in the presence of a thermal power transferred by the lamps equal to $\dot{Q}^*$ and a reference temperature difference $DT^*_ref,n = \frac{\dot{Q}^*}{k}$, that depends to the number of revolutions used for the regulation. As the number of revolutions at the start of the thermal process is equal to 10 rpm, we get:

$$T_{sensor,2\pi} = T_{1}^* (0,2\pi) = DT^*_ref,n=10 \cdot 0^*(0,2\pi)+T_0 \quad (26)$$

with $T_{1}^*(0,\tau)$ representing the temperature read by the pyrometer in the first period. Using Eq. (22), the target temperature is determined for the period $4\pi$, and the temperature target fluctuation $\Delta T_{targ,4\pi}$ is then determined (Eq. (23)):

$$\Delta T_{targ,4\pi} = T_{targ,4\pi} - T_{sensor,2\pi} = 11.1^\circ C \quad (27)$$

Finally, by means of Eq. (24), particularized at time $\tau = i + 2\pi$, the correct value of $n$ is obtained (Figure 8).

$$\Delta T_{targ,4\pi} = \Delta T_{targ,4\pi} + \text{err}2\pi/2 = 27.206 \cdot n^{0.5} + 4.651 \cdot 10^{-17} \cdot n \quad (28)$$

A number of revolutions is chosen which, in the period between $2\pi$ and $4\pi$, achieves a $\Delta T_{targ,4\pi}$ necessary to reach the target temperature at $4\pi$, entered to consider the fact that the starting temperature is lower than in the reference case (+ err/2). By examining the second period to the Table 6 ($\tau = 2\pi-4\pi$), we can observe that the sensor temperature is:

$$T_{2\pi}^*(0,4\pi) = DT^*_ref,n=5 \cdot 0^*(0,4\pi)+T_0 = 41.7^\circ C \quad (29)$$

the target temperature is:

$$T_{targ,4\pi} = 42.7^\circ C \quad (30)$$

It is observed how the error decreases from $\text{err}2\pi =2.5 ^\circ C$ to $\text{err}1\pi =1 ^\circ C$. Proceeding in a similar manner for all periods, the temperature profile shown in Figure 10 is obtained.

It can also be noted that the average temperature obtained from the regulated temperature profile Eq. (31) and that relating to the reference Eq. (32) case are generally the same, with only a very small error (Figure 11, Table 7).

$$\bar{T}_{reg} = \frac{1}{2\pi} \int_0^{2\pi} \theta^*(0,\tau) \cdot DT^*_ref,n_p + T_0 \quad (31)$$

with $n_p$ indicating the number of revolutions selected for each period (Table 6).

$$\bar{T}_{targ} = \frac{1}{2\pi} \int_0^{2\pi} \theta^*(0,\tau) \cdot DT^*_ref,10 + T_0 \quad (32)$$

</table>
The maximum error is obviously detected at the end of the first period when the regulation system has not yet intervened.

Thus, even though the set-up conditions are different, a peeling process has been got that's entirely similar to the individual thought-out optimum, both in thermal conditions and in terms of quality. We can recap it as follows (Figure 12):

1. Known the optimal value of \( n \), the peeling process starts.
2. At the end of the \( i \) period, through Eq. (21), we extract the \( T_{\text{targ, i+2n}} \) and through the pyrometer the temperature of tomato.
3. Eq. (23) allows us to calculate the temperature jump required to reach the target temperature at the next period, while Eq. (22) the error.
4. Using Eq. (24), the number of revolutions for the following period is obtained

5. Conclusion
   After having carried out a preliminary study and having obtained the value of the rotation speed, and therefore of the temperature profile, which makes it possible to obtain a peeling of excellent quality, at the chosen set-up (distance and power of the IR lamp, average diameter of the tomatoes, etc.), it is important to put in a logic of control which allows us to obtain a conforming to that sought when the set-up conditions vary. Any cause that takes us away from pre-established conditions, for example a diameter of the tomato lower than that tested in the preliminary study, can be assimilated to a variation in thermal power exchanged between the lamp IR and tomato. In particular, the surface temperature of the tomato has a lower profile than the reference one if the thermal power is lower, vice versa in the opposite case. Therefore, to obtain the same temperature profile for the peeling process, a control logic has been put in place which allows the thermal power between the IR lamp and the tomato to be varied by adjusting the number of revolutions. Through the study of the analytical model and the approximate solution, an estimate of the amplitude of temperature fluctuations \( \Delta T(n) \) for each period as the number of revolutions varies was obtained. Consequently, the Eq. (24) is used to determine the value of the number of revolutions for the following period after evaluating the temperature error between the sensor temperature and the target temperature (obtained from the approximated solution) at each period and the temperature jump required to reach the target temperature at the next period. This results in a standardized peeling process in terms of process time, temperature and quality.

### Nomenclature

- \( \rho \): Mass density, \( \text{Kg m}^{-3} \)
- \( c_p \): Specific heat, \( \text{J kg}^{-1} \text{K}^{-1} \)
- \( \alpha \): Thermal diffusivity, \( \text{m s}^{-2} \)
- \( k \): Thermal conductivity, \( \text{W m}^{-1} \text{K}^{-1} \)
- \( \Omega \): Period, \( \text{s} \)
- \( n \): Number of revolution, \( \text{rpm} \)
- \( X_{\text{volume}} \): Volume fraction
- \( X_{\text{mass}} \): Mass fraction
- \( \tau \): Dimensionless temperature
- \( \theta \): Dimensionless time
- \( \xi \): Dimensionless x
- \( \text{Bi} \): Biot number
- \( \varepsilon \): Emissivity
