**Abstract**

**Objectives:** The role of alpha-lipoic acid in the amelioration of iron overload-induced hepatic damage remains largely under-explored. Therefore, this paper aimed at describing the structural effects of alpha-lipoic acid on the liver following iron overload in mice.

**Methods:** After ethical approval, a total of 24 male mice were used. Twenty mice were randomly divided into two groups: A and B. Group A rats received 50 mg/kg of iron dextran intraperitoneally daily for 49 days, while those in Group B received a daily oral dose of 100 mg/kg alpha-lipoic acid by gavage in addition to the treatment in Group A. Four mice were used as normal controls. At the endpoint of the experiment, the livers were harvested and studied for iron deposition, parenchymal histoarchitecture and hepatocyte densities. Photomicrographs were taken using a digital photomicroscope for morphometric analysis.

**Results:** Treatment of mice with iron led to a distortion of the histoarchitecture of the liver which was attenuated with co-administration of alpha-lipoic acid. Additionally, co-treatment of iron with alpha-lipoic acid resulted in significant lowering of hepatic iron deposition (*p*<0.001), reduction in leukocyte infiltration and significantly greater hepatocyte densities (*p*<0.001).

**Conclusion:** Alpha-lipoic acid considerably attenuates the structural damage in the liver induced by iron overload.

**Keywords:** alpha-lipoic acid; iron; liver

**Introduction**

Iron overload is a common clinical problem that occurs in conditions such as hereditary hemochromatosis and transfusion dependent anaemia including sickle cell disease and beta thalassemia. Since the liver is the main storage site for iron, it is among the key organs to be adversely affected by iron overload toxicity resulting in hepatic fibrosis and hepatocellular necrosis.

Currently, management of iron overload involves iron chelation therapy and phlebotomy. These modalities however, have several limitations including high cost, patient inconvenience and numerous associated side effects. Furthermore, phlebotomy is contraindicated in anaemic patients. Thus, there is need for better avenues to augment the management of iron overload. Alpha-lipoic acid (ALA) is a widely available cheap but potent antioxidant. It has lately been in use in the management of diabetic polyneuropathies where it scavenges reactive oxygen species (ROS) produced as a result of glucose auto-oxidation induced by hyperglycemia. A few studies have documented the possible iron chelating properties of ALA. For instance, Goralska et al. showed that treating isolated cultured lens epithelial cells with ALA significantly lowered the size of the free intracellular iron. In another study by Suh et al., feeding ALA to aged rats for 2 weeks showed a reversal of the age-related accumulation of iron in the cerebral cortex. However, these studies were conducted under conditions of normal body iron levels. Hitherto, there are hardly any studies that have investigated the effects of ALA on the liver following iron overload. This study therefore...
aimed to describe the structural effects of ALA on the liver of the mouse following iron overload.

**Materials and Methods**

ALA was supplied by Nature’s Bounty, Inc. (Bohemia, NY, USA) while iron dextran (Dawafer) was supplied by Chongqing Fangtong for Dawa Limited (Kenya). The injections were administered using 30 gauge (BD Micro-Fine™ Plus; Becton Dickinson and Co., Franklin Lakes, NJ, USA) insulin syringes and a gavage tube for mice was used for oral drug administration.

A total of 24 male 8 week old mice (*Mus musculus*) were purchased from The Department of Zoology, University of Nairobi, Kenya. Ethical approval to conduct the study was obtained from the Animal Use and Ethics Committee, Faculty of Veterinary Medicine, University of Nairobi, Kenya. The handling and care of the animals were in accordance with the guidelines provided by the same committee.

Four mice were randomly selected for use as normal controls. One of the 4 mice selected as controls was used to show the baseline histomorphology of the liver. The remaining 20 mice were then randomly divided into two equal groups: A and B. Group A received a daily intraperitoneal (i.p.) injection of 50 mg/kg/day of iron dextran followed by daily oral gavage of 0.3 ml of normal saline, while Group B received a daily i.p. injection of 50 mg/kg/day iron dextran followed by daily oral gavage of 100 mg/kg/day of ALA. The normal control mice were given a daily i.p. normal saline (30 μl) followed by daily oral gavage of 0.3 ml normal saline. The dose of iron dextran used was based on the study by Zhang et al.,[12] while that of ALA was based on the studies by Budin et al.[13] and Ahmadvand and Jamor.[14] Three mice from each group were sacrificed at day 16 and 32 of the experiment while the remaining 4 in each group were sacrificed at day 49.

The livers were harvested en masse and stored in 10% formalin. Independent uniform random sampling, as described by Marcos et al.,[15] was used to select 5 random fragments from each liver for histological processing and staining with haematoxylin and eosin.

Photomicrographs of the stained sections were taken using a 12 mega pixel Canon camera mounted on a photomicroscope.

Estimation of iron deposition was done using the Cavalieri’s principle of point counting.[16] Using the Image J software, grid squares were superimposed on the images then the cells within a square and those crossed by the inclusion line were counted (Figure 2).

Quantitative data on volumetric densities of iron deposits and hepatocyte densities was entered into the Statistical Package for Social Sciences (SPSS for Windows, version 21.0; SPSS Inc., Chicago, IL, USA) for analysis. Cell densities were expressed in mm2 while iron deposition was expressed as a percentage. Kruskal-Wallis H test was used to compare medians of the quantitative data across the various harvesting periods within each group while Mann-Whitney U test was used to compare the medians between Group A and B. A p value ≤0.05 was considered significant at 95% confidence interval. Data are presented in photomicrographs and graphs.

**Results**

Iron treatment resulted in a progressive increase in the volumetric densities of the iron deposits from 6.4% at day 16 to 12.03% and 27.26% at days 32 and 49, respectively (p<0.001). Co-administration of iron with ALA resulted in

![Figure 1](https://www.anatomy.org.tr)

**Figure 1.** The point counting method to estimate the volumetric density of the iron deposits. The volume densities of the iron deposits were calculated by the formula $V_v = P_p/P_t$, where $V_v$ is the volume density, $p$ is the component under consideration (iron deposits), $P_p$ is the number of test points associated with $p$, and $P_t$ is the total number of points of the test system. [Color figure can be viewed in the online issue, which is available at www.anatomy.org.tr]
significantly lower volumetric densities across all the harvesting periods (p<0.001). The percentages in the ALA group were 3.76%, 7.52% and 15.79% at day 16, 32 and 49, respectively (Figure 3).

Iron treatment resulted in distortion of the normal hepatic histoarchitecture proportional to the duration of treatment. There was marked degeneration of hepatocytes with distortion of the hepatocyte cords. The nuclei of hepatocytes were enlarged and showed fragmented nucleoli. There was also infiltration of deeply basophilic leukocytes around several clusters of large iron deposits.

ALA co-administration resulted in a reduction of the magnitude of the iron overload induced histoarchitectural changes as evidenced by the reduction in the sizes and area of the iron deposits. The cord like arrangement of the hepatocytes was also preserved with discernible boundaries between cells in adjacent cords. The nuclei of hepatocytes showed less enlargement and fragmentation. The leukocyte infiltrates were also reduced (Figure 4 a–f).

Iron treatment resulted in a progressive decline in the hepatocyte densities from 1433.33/mm² at day 16 to 1383.33 and 689.89/mm² at day 32 and 49 respectively (p<0.001). Time matched mice treated with iron and ALA showed higher hepatocyte densities compared with the mice treated with iron alone (p<0.001). The densities for the mice treated with iron and ALA were 1572.22, 1583.33 and 1055.56/mm² at day 16, 32 and 49 respectively (Figure 5).

Discussion

ALA reduced the hepatic iron deposition in a manner similar to previous studies using related compounds. For instance, Gao et al.[19] reported a reduction in iron deposition on the mouse liver using danshen, an antioxidant compound. The reduction in iron deposition with ALA treatment could be attributed to its iron chelating properties.[20] This is a similar mechanism to that of deferoxamine and deferipone, known iron chelators that have been shown to reduce hepatic iron deposition in mice liver following iron overload.[21] The dithiolane ring in the chemical structure of ALA confers its ability to bind redox active elements such as iron.[20,22] Since generation of ROS directly correlates with the concentration of free intracellular iron,[23] administration of ALA to iron overload patients could help chelate this free intracellular iron and thus reduce ROS generation and hepatic damage.

ALA treatment, as with other interventions reported elsewhere, resulted in a reduction in the parenchymal damage seen with iron overload. Hazra et al.[24] noted that a flavonoid compound, Katha, was protective against iron overload induced liver damage, while Sarkar et al.[25] studied the effects of *Emblica officinalis*, an antioxidant, on the mouse liver following iron overload, and also noted an improvement in the histoarchitecture compared with iron treatment alone. The reduction in parenchymal damage may be attributed to the antioxidant capacity of ALA which makes it able to scavenge ROS produced during iron overload.[20] Systemic ALA has been shown to be protective against light induced oxidative retinal damage, supporting its protective effects against oxidative damage.[26] This is further supported by
Alpha-lipoic acid reduces iron overload-induced structural changes in the liver
