Abstract

Objective: The current study aims to investigate different inter-stimulus interval effect on habituation process by using non-painful tactile stimuli.

Methods: Twelve right-handed healthy volunteers (6 female; mean age: 22.9 ± 1.93 years) participated to the study. The electroencephalography (EEG) was recorded from 64 channels. Non-painful tactile stimuli (~ 140 kPa) were delivered to the right index finger via using a pneumatic stimulator. Somatosensory evoked potentials (SEP) paradigm was used in all session. Inter-stimulus interval (ISI) was selected as 2s, 4s, and 8s and applied in separate sessions (as ISI_2 , ISI_4 and ISI_8).

Results: Peak-to-peak maximum amplitudes of N2, P3 and N4 components were measured for three different ISI and for three different electrode sites (Fz, Cz, Pz). The 3x3 repeated measures ANOVA test was employed for statistical analysis. According to the analysis, a significant inter-stimulus interval (ISI) effect was found on both $PPmax_{N2P3}$ and $PPmax_{P3N4}$ ($p=0.004$ and $p=0.001$ respectively). The amplitudes of ISI_8 session in all electrode sites higher than ISI_2 session for both $PPmax_{N2P3}$ ($p=0.024$) and $PPmax_{P3N4}$ ($p=0.012$). Also, ISI_4 session has higher amplitudes than ISI_2 session ($p=0.05$) for the $PPmax_{P3N4}$.

Conclusion: This study revealed that the late components of SEPs are affected by the ISI change. The amplitudes of SEP components are increased as ISI increased.

Keyword: Non-painful tactile stimuli, habituation, inter-stimulus interval, electroencephalography.

INTRODUCTION

The phenomenon of habituation has been observed during the process of repetitive stimuli within a wide range of organisms from amoeba to highly organized organisms such as amphibians, reptiles, birds, humans and some plants¹. This process basically prevents cortical areas from the irrelevant information and this way organism can save time and energy to distinguish the relevant sensory inputs from the multisensory world². The studies generally focused to the habituation mechanisms of human auditory and visual systems. Despite the importance, especially during the perception of the outside world from the early stage of life-span³ include variety in sensation such as pressure, pain, temperature and muscle sense, habituation mechanisms of human somatosensory system was studied in a relatively few number of studies. Generally, somatosensory perception and the possible habituation mechanisms are investigated by

using the painful or mechanical (electrical, laser, heat, vibration and rotation) stimuli in the literature⁴⁻⁸.

Nowadays, with the development of the technology, the haptic feedback became a very important topic in scientific research including the invasive surgery, electromechanical graphics and haptics added to mobile phones and large-scale displays. Beyond the haptic feedback, the basic habituation mechanisms of the tactile or touch stimuli became to an important topic for the researchers⁹. It is known that the cortical responses to tactile (non-painful) and nociceptive (painful) processing have different temporal and spatial activation patterns¹⁰⁻¹². But the habituation mechanisms of tactile stimulation are not clear yet in regard to electrophysiology. Inter-stimulus interval manipulation is one of the valid methods to investigate the habituation on somatosensory perception in healthy individuals and patients¹³. In these studies, the

pain habituation has been studied well but the effects of inter-stimulus interval on habituation by using touch stimulus have not been investigated until now.

In this context, the current study aimed to investigate the effect of different inter-stimulus interval on the habituation process by using non-painful tactile stimulation.

METHODS

Twelve right-handed healthy volunteers (6 female; mean age: 22.9 ± 1.93 years) participated to the study. The handedness was evaluated by a Turkish version of the Edinburgh Handedness Inventory. None of the participants have any self-reported neurological, psychological or chronic diseases. The local ethical committee of the university approved the study (EK2018/12-29) and all of the participants signed the informed consent before the attendance to the study.

Brain responses recorded via 64 channel electroencephalography (EEG, Neuroscan 4.2, Synamps, USA) while participants were seated in a comfortable chair in a room with an electromagnetic shield and sound isolation. Embedded Microcontroller Stimulation Unit (EMISU)¹⁴ and additional equipment such as video recording system and analysis computer were used during the recordings.

For the EEG recordings a specific 64 channel cap (Quik Caps, Compumedics, USA) was used and were placed according to the international 10-10 electrode positions system¹⁵. For the references, earlobes were linked $[(A1+A2)/2]$ with Ag/AgCl electrodes. Additionally, Ag/AgCl electrodes were placed to the outer canthus of the left and right eyes for the electrooculography (EOG) recordings to monitor the eye movements. Both the reference and EOG electrodes were filled with the EEG paste (EEG Paste-z401CE, Japan), while the cap electrodes were filled with the EEG gel (Neurogel-Genova/Italy) to reduce the

impedance. All impedance values were kept under the 10 k Ω .

Non-painful tactile stimulations were delivered via a pneumatic stimulation unit (Somatosensory Stimulus Generator 4-D Neuroimaging, USA) and was applied to the index finger pulp of the right hand via clips which have moving membrane under the constant air pressure (Figure 1). The air pressure for the stimulus was set at ~ 140 kPa. The time of the delivered stimulus to the subject was marked to the EEG for the offline analysis.

Figure 1: Non-painful tactile stimulus delivered via clips which has been demonstrated in the figure. (A) is the membrane without stimulus, (B) with stimulus in the clips and (C) while the finger is placed.

Participants came to the laboratory in two different days. In the first day, the environment of the EEG room and the experimental protocol were introduced to the participants. In the second day, all participants filled the forms (incl. informed consent and personal information form) and scales (incl. Edinburgh Handedness Test, Epworth Sleepiness Scale, The State Trait Anxiety Inventory-STAI-TX1) and they attended to the whole experimental procedure. Somatosensory evoked potential (SEP) paradigm was used in all recordings. Inter-stimulus interval (ISI) was selected as 2s, 4s, and 8s and applied as separate sessions with a randomized order for each participant. The stimuli were presented as 40 times in each session and total stimulus duration 200 ms. Therefore, all participants received a total of 120 stimuli. Additionally, there was approximately 5 minutes resting period

between the sessions. During the recordings, the subjects were instructed to keep their eyes at a fixation point located on the computer screen and ignore the stimuli.

For the sake of simplicity, three electrodes (Fz, Cz, and Pz) were analyzed primarily. Off-line analysis was conducted to reveal the brain responses to the non-painful tactile stimuli. The off-line analysis procedure contains cutting epochs, baseline correction, artefact rejection, filtering and averaging. As a first step, eye blinks and eye movements were extracted from the continuous EEG by using a tool, based on Independent Component Analysis, on the Scan 4.5 software (Neuroscan Inc., USA). Then, the epochs were created by cutting the continuous data from -1000ms (pre-stimulus) to 1000ms (post-stimulus). The epochs, which contained greater than $\pm 50 \mu\text{V}$ amplitudes were also rejected. Then, remaining epochs were corrected to the baseline by using pre-stimulus interval and filtered with a 0.5 – 48 Hz band-pass filter (12 dB/octave gain and zero phase shift). In the last step of the analysis, the individual average files were created and they were used for the peak to peak maximum (PPmax) amplitude measurements. In the literature, there are many different notations for the SEP components. In this study we demonstrate the peaks N200 as N2, P300 as P3 and N400 as N4. Therefore, the $\text{PPmax}_{\text{N2P3}}$ and $\text{PPmax}_{\text{P3N4}}$ calculated by subtracting the amplitude of N2 from the amplitude of P3 and N4 from P3 respectively (See Figure 2).

Statistical Analysis

SPSS software (v24, IBM, USA) was employed for the statistical analysis. A two-way 3x3 repeated measures ANOVA (rm-ANOVA) was applied for the statistical evaluation. The peak-to-peak maximum amplitudes were measured for three different inter-stimulus intervals (2s, 4s, and 8s) in three different electrode locations (Fz, Cz and Pz). ISI and electrode

positions were analyzed as within subject factors. In all cases, the sphericity was maintained. Significance level was selected as 0.05 for all comparisons. Additionally, Bonferroni correction was applied to the pairwise comparisons.

Figure 2: Grand averages of Somatosensory Evoked Potentials (SEP) are demonstrated in Cz electrode for three inter-stimulus interval sessions (2s, 4s, and 8s). The horizontal axis denotes times in seconds, while the vertical axis denotes amplitudes of responses to non-painful tactile stimuli in microvolts (μV). Time zero "0" represents the stimulation time. Peak to peak amplitude measurements were done according to the N2, P3 and N4 components.

RESULTS

$\text{PPmax}_{\text{N2P3}}$ and $\text{PPmax}_{\text{P3N4}}$ amplitudes were measured for all participants in three different electrodes and three different ISI sessions. According to the rm-ANOVA, a significant inter-stimulus interval (ISI) effect was found on both $\text{PPmax}_{\text{N2P3}}$ $F(2,22)=7.17$; $\eta^2=.395$; $p=0.004$ and $\text{PPmax}_{\text{P3N4}}$ $F(2,22)=8.93$; $\eta^2=.448$; $p=0.001$. To reveal the significant differences between the ISI's, pairwise comparisons were employed. According to these comparisons, ISI_8 session has significantly higher amplitudes than ISI_2 session ($p=0.024$), and the amplitudes of ISI_4 session is higher than the ISI_2 sessions' ($p=0.05$) in all electrode areas for the measurements of $\text{PPmax}_{\text{N2P3}}$. For the measurements of $\text{PPmax}_{\text{P3N4}}$, pairwise

comparisons indicated that ISI₈ session has significantly higher amplitudes than ISI₂ session ($p=0.012$). ISI₈ session has the highest amplitudes for all electrode sites (Fz, Cz and Pz) in both measurements of for PPmax_{N2P3} and PPmax_{P3N4} (Figure 3). An increase in amplitudes to non-painful tactile stimuli was observed with the increase of the inter-stimulus interval for both PPmax_{N2P3} and PPmax_{P3N4} (Figure 2). Despite the significant amplitude differences, there were no significant effects of electrodes and ISI / electrode interaction in regard to rm-ANOVA results.

Figure 3: The mean amplitudes of PPmax_{N2P3} (A) and PPmax_{P3N4} (B) were demonstrated for three inter-stimulus interval (2s, 4s and 8s) sessions in three electrode areas (Fz, Cz, Pz). White bars represent the ISI₂ session, gray bars represent the ISI₄ and black bars represent the ISI₈ session.

DISCUSSION

The current study aimed to reveal the habituation process on somatosensory system by investigating the brain responses to the non-painful tactile stimuli with different inter-stimulus intervals (ISI) 2s, 4s, and 8s. Accordingly, the present study revealed that as ISI prolonged the amplitudes increased. In the literature, studies revealed an increase in amplitudes as the ISI increased by using the painful^{5,8,16,17}, vibration⁶ or mechanical (rotation of the hand) stimuli⁴. These stimuli were generally applied to the hand, wrist, arm or leg. In the present study, non-painful tactile stimuli applied to the fingertip. When the stimulus type is considered, electrical stimuli

can be evaluated as unnatural. Tactile stimulus is simple and more relevant to the daily life sensory transmission and might be comfortable for the participant compared to the electrical stimuli. Despite the similar neural pathways are involved to the signal transduction, from receptors to the brain, the context of the electrical and tactile stimulus can be evaluated very differently in regard to perception.

In the real world, we are trying to detect the change of the stimulus parameters during the perception. During these processes the hands provides complex interaction with the environment and behave like a sensory detector¹⁸. People are touching and describing the objects via their fingers neither their elbows nor the wrists¹⁹. Hence, the stimulation from the elbow, wrist or arm can be evaluated as artificial stimuli, while the stimulus used in the current study was evaluated as a simple touch which was defined as “baby touch” by most of the participants. Non-painful tactile stimulus delivered to limited area of the fingertip. Thus, stimulation of more than one nerve fiber and muscle group was avoided.

In the literature, somatosensory evoked potentials (SEP's) and somatosensory evoked fields (SEF's) were used to investigate habituation process due to the nature of experimental design which contains repetitive stimulations. In one of the oldest studies about the habituation process, mechanical stimuli (rotational) was delivered to the wrist with the different ISIs (0.5s, 1s, 2s, 4s, 8s, and 16s), and as a result, larger ISIs associated with the increased amplitudes⁴.

In another study, possible habituation process was investigated via the painful laser stimuli with different inter-stimulus intervals including 0.5, 1, 2, 4, 8, and 16 seconds. According to the peak-to-peak maximum amplitude measurements, they revealed a significant increase in the amplitudes from the ISI-1s session to ISI-2s session and also from ISI-2s

session to ISI-4s session. Also, there was a general increase in amplitudes with longer ISIs but these increments were not significant²⁰. The studies in which electrical and vibrotactile stimuli were applied to the finger, amplitude increased as ISI increased²¹. The study which performed by Tomberg et al. showed that the N30 component amplitude increased as ISI increased. But there were no significant peak differences (N20, P27, N60, P100 and P200) in long ISIs (1400, 2500 and 4000 ms). These studies tried to evaluate the very early and early components of SEP's or SEF's to reveal the habituation process on somatosensory system. In addition to the literature, the present study evaluated the relatively late components of SEP's including the N200, P300 and N400. Current study revealed an amplitude increase when the ISI's (2s, 4s and 8s) are increased. This finding is in line with the previous findings in regard to studies investigated the SEP's and SEF's. In the present study significant increase of the amplitudes were measured between the ISI₂ and ISI₈ session.

These findings might be explained by the different type of stimulus. Moreover, very early and early components might be the affected peaks due to the electrical or vibration stimulation, while the late components (N2, P3 and N4) might be the affected peaks due to the non-painful tactile stimuli. Indirectly, it is possible to speculate that the habituation can be observed in the late components of SEP's during the perception of tactile stimuli.

Additionally, there were no significant increase after 4000 ms of ISI in the literature^{20, 21}. But current study showed a significant increase in the 8000 ms of ISI in comparison with the 2000ms. In our preliminary study we also spotted a 66% increase of amplitudes in ISI₁₆ compared with the ISI₂. Therefore, we conclude that the significant differences can be observed when the differences between the ISIs were at least four times bigger than each other. To

clarify these theories, further studies needed in terms of different ISI's setup.
