Abstract: This paper presents two alternate formulas for estimating attributable risk (AR). One of the formulas provides another interpretation of AR and leads to the discovery of relative attributable risk (RAR), a refined measure of attributable risk. It has been proved that RAR has a number of appealing theatrical properties. In this paper, some applications of RAR in case-control studies with stratification will be explored and a real set of data on esophageal cancer study will be used to demonstrate the advantages of the RAR.

1. Introduction

The attributable risk, which has also been referred to various names such as the attributable fraction [5] and population attributable risk percent [2], provides an estimate of the proportion of cases that are related to a given exposure. It is usually interpreted as the fraction of disease in a population that might be avoided by reducing or eliminating exposure to an etiologic agent, provided that it is causative [9]. The information gained from AR estimates may contribute to the choice of disease prevention strategies for the public health. Studies of AR can be dated back to the early 1950s [4].
